Abstract

Triangle finding (deciding if a graph contains a triangle or not) is a central problem in quantum query complexity. The quantum communication complexity of this problem, where the edges of the graph are distributed among the players, was considered recently by Ivanyos et al. in the two-party setting. In this paper we consider its \( k \)-party quantum communication complexity with \( k \geq 3 \). Our main result is a \( \tilde{O}(m^{7/12}) \)-qubit protocol, for any constant number of players \( k \), deciding with high probability if a graph with \( m \) edges contains a triangle or not. Our approach makes connections between the multiparty quantum communication complexity of triangle finding and the quantum query complexity of graph collision, a well-studied problem in quantum query complexity.

1 Introduction

Triangle finding. A triangle in an undirected graph \( G = (V, E) \) is a set of three vertices \( v_1, v_2, \) and \( v_3 \) such that \( \{v_1, v_2\}, \{v_1, v_3\}, \) and \( \{v_2, v_3\} \) are edges. The problem of deciding whether a given graph contains a triangle or not is called triangle finding, and has been the subject of thorough investigations in the past years in both the classical and quantum settings.

In the classical setting, several new applications of this problem have been discovered recently. In particular, Vassilevska Williams and Williams [20] showed in 2010 a surprising reduction from Boolean matrix multiplication to triangle finding. Several works followed (e.g., [17, 21]), which have now placed triangle finding as a central problem in the recent theory of fine-grained complexity.

In the quantum setting, triangle finding has played a prominent role in the development of quantum query algorithms. For query algorithms solving graph-theoretic problems like triangle finding, information about the set of edges \( E \) can be obtained only by queries to an oracle representing the adjacency matrix of the input graph: given two vertices \( u \) and \( v \) of \( G \), the oracle outputs one if \( \{u, v\} \in E \) and zero if \( \{u, v\} \notin E \) (in the quantum setting the queries can naturally be done in superposition). The trivial upper bound on the quantum query complexity of triangle finding is \( O(n^{3/2}) \), where \( n \) denotes the number of vertices of the graph, by Grover search. A series of works spreading over more than a decade [4, 7, 10, 12, 14, 16] successively improved this bound to \( O(n^{5/4}) \) by using more advanced techniques like quantum walks, learning graphs, variable costs quantum search and quantum nested walks. On the other hand, the best known lower bound on the quantum query complexity of triangle finding is the trivial \( \Omega(n) \). Understanding whether the \( O(n^{5/4}) \) upper bound is tight or not is now the main open problem concerning the quantum query complexity of triangle finding in dense graphs. Several quantum query algorithms for triangle finding over sparse graphs have been constructed as well [6–8, 13].
Communication complexity of triangle finding. In this paper we consider triangle finding not in the quantum query complexity model, but in the quantum communication complexity model. As usual when considering graph-theoretic problems in the communication complexity setting, we assume that the edges of the graphs are distributed among the players (in this paper we consider the most general case where the subsets of edges owned by the players can overlap). In the two-party case, for instance, the first player Alice receives a set of edges $E_A \subseteq E$ and the second player Bob receives a set of edges $E_B \subseteq E$ such that $E_A \cup E_B = E$ (the intersection of these two sets is not necessarily empty). The players must decide if the whole graph contains a triangle or not. We will use $\text{TF}^k_{n,m}$ to denote this distributed version of triangle finding, where $k$ represents the number of players, $n = |V|$ and $m$ is an upper bound on $|E|$.

The problem $\text{TF}^2_{n,n^2}$ has been studied by Ivanyos et al. [9] and is well understood: its bounded-error quantum communication complexity is $\Omega(n)$. Indeed, it is easy to see that in the two-party setting triangle finding reduces to the computation of the disjointness function $\text{DISJ}_{n',n}$ with $n' = n^2$. The upper bound then follows from the $O(\sqrt{n'})$-qubit protocol by Aaronson and Ambainis for disjointness [1]. The lower bound follows by combining the observation that conversely disjointness can be reduced to triangle finding with the $\Omega(\sqrt{n'})$-qubit lower bound on the quantum communication complexity of disjointness [19]. More generally, for possibly sparse graphs, the bounded-error quantum communication complexity of $\text{TF}^2_{n,m}$ is $\Theta(\sqrt{m})$. Note that the classical bounded-error communication complexity of this problem is $\Theta(m)$: the upper bound follows from the trivial protocol where Alice sends all her input to Bob and the lower bound follows from lower bounds on the classical communication complexity of disjointness [11, 18].

Our contributions. In this paper, we consider the three-party quantum communication complexity of triangle finding, i.e., the problem $\text{TF}^3_{n,m}$ where the edges of the graph are distributed among three players (Alice, Bob and Charlie). In the classical bounded-error communication complexity setting, the communication complexity of this problem is again $\Theta(m)$, since it is not easier than the two-party case (we can consider that one player has no edge as input). To our knowledge the quantum communication of this problem has never been studied before the present work.

Note that the communication complexity of $\text{TF}^k_{n,m}$ for any constant $k > 3$ is equal (up to possible constant factors) to the communication complexity of $\text{TF}^3_{n,m}$, which further motivates the study of the latter problem. Indeed, the former problem is again obviously not easier than the latter problem and, conversely, since a triangle consists of three edges, in the $k$-party case we can apply a protocol for the $3$-party case independently for each triple of players (the number of such triples is constant if $k$ is constant) in order to decide whether the whole graph has a triangle or not.

Our main result is the following upper bound.\footnote{The disjointness function $\text{DISJ}_{n',n}$ in the two-party setting is the following problem: Alice has a subset $x \subseteq \{1, \ldots, n'\}$, Bob has a subset $y \subseteq \{1, \ldots, n'\}$, and they want to decide if $x \cap y \neq \emptyset$.}

**Theorem 1.** The bounded-error quantum communication complexity of $\text{TF}^3_{n,m}$ is $\tilde{O}(m^{7/12})$.

Let us briefly explain the main ideas that lead to the construction of our quantum protocol showing Theorem 1. The main part of the protocol consists of procedures simulating the quantum query algorithm for graph collision by Magniez, Santha, and Szegedy [16]. Indeed, for the dense case (i.e., $m \approx n^2$), it is fairly easy to see that a simple combination of a procedure implementing Grover search and another procedure simulating (in the communication complexity setting) the $O(n^{2/3})$-query algorithm for graph collision by Magniez, Santha, and Szegedy [16] gives the claimed $\tilde{O}(n^{7/6})$ upper bound. For sparse graphs, a first observation is that a quantum query algorithm for graph collision exploiting the sparsity of the given graph would help us to design an efficient quantum communication protocol for three-party triangle finding. However, whether graph collision can be solved with $O(n^{2/3-c})$ queries for some constant $c > 0$ even for $m = n^{4/3}$ (i.e., even when the graph is significantly sparse) is a long-standing open problem. To overcome this difficulty, we consider a variant of graph collision and simulate,
exploiting the fact that each player completely knows a subset of edges in our setting of communication complexity (which is not true in the query complexity setting), a quantum algorithm for it. We also divide the set of vertices of the graph into two sets: the set of vertices with degree smaller than \( n^s \) and the set of vertices with degree larger than \( n^s \), where \( s \) is a parameter. This classification helps us, via Ambainis' variable costs quantum search technique [3], to reduce the communication cost needed to simulate the quantum algorithm for the variant of graph collision.

Next, we investigate whether the upper bound of Theorem 1 is tight. The trivial lower bound on the bounded-error quantum communication complexity of \( TF^3_{n,m} \) is \( \Omega(m) \), in particular showing that the bounds of Theorem 1 are optimal for some value of \( m \).

\[ \Omega(n^{1/2}) \]

Proposition 1.2. It thus still remains possible that in the sparse regime the trivial lower bound on the bounded-error quantum communication complexity of \( TF^3_{n,m} \) would imply an improvement over \( \Omega(n^{7/6}) \) for \( TF^3_{n,m} \) (since we can apply Theorem 1 with \( n = \sqrt{m} \)). We also show the following sparse version of Proposition 1.1:

**Proposition 1.2.** If the bounded-error quantum communication complexity of \( TF^3_{n,m} \) is \( \Omega(m^{4/7} + \epsilon) \) for some \( m \) (seen as a function of \( n \)) and some \( \epsilon > 0 \), then the quantum query complexity of graph collision is \( \Omega(n^{1/2 + \delta}) \) for some \( \delta > 0 \).

Proposition 1.2 shows that giving a lower bound of the form \( \Omega(m^{4/7} + \epsilon) \) for some value \( m < n^2 \), and in particular showing that the bounds of Theorem 1 are optimal for some value of \( m \), would also lead to a significant breakthrough. Note nevertheless that there is a gap between the best lower bound \( \Omega(\sqrt{m}) \) on the bounded-error quantum communication complexity of \( TF^3_{n,m} \) and the quantity \( \Omega(m^{4/7}) \) from Proposition 1.2. It thus still remains possible that in the sparse regime the trivial lower bound \( \Omega(\sqrt{m}) \) can be improved without any impact on the quantum query complexity of graph collision.

## 2 Preliminaries

### 2.1 Quantum communication complexity

Let \( A_1, \ldots, A_k \) be \( k \) finite sets. Consider \( k \) players and assume that for each \( i \in \{1, \ldots, k\} \) the \( i \)-th player receives as input an element \( a_i \in A_i \). In the model of communication complexity, first introduced in the classical two-party setting by Yao [22], the players want to compute a function \( f : A_1 \times \cdots \times A_k \to \{0,1\} \) by running a protocol such that, at the end of the protocol, each player outputs \( f(a_1, \ldots, a_k) \), and they want to minimize the communication they need to compute the function \( f \). In the quantum communication model, introduced by Yao [23], the players are allowed to communicate with qubits. More precisely, the quantum communication complexity of a quantum protocol \( P \) is the maximum (over all inputs) number of qubits that \( P \) sends. The bounded-error quantum communication complexity of \( f \) is the minimum communication complexity of any quantum protocol that computes \( f \) with probability (over the random coins used by the protocol) at least 2/3.

### 2.2 Quantum query complexity of graph problems

For any finite set \( S \) and any \( r \in \{1, \ldots, |S|\} \) we denote \( \mathcal{X}(S, r) \) the set of all subsets of \( r \) elements of \( S \).
Let $G = (V, E)$ be an undirected and unweighted graph, where $V$ denotes the set of vertices and $E$ denotes the set of edges. In the quantum query complexity setting, we only access the set of edges $E$ through a quantum unitary operation $O_G$ defined as follows. For any pair $\{u, v\} \in V(V, 2)$, any bit $b \in \{0, 1\}$, and any binary string $z \in \{0, 1\}^*$, the operation $O_G$ maps the basis state $|\{u, v\}\rangle|b\rangle|z\rangle$ to the state

\[
O_G|\{u, v\}\rangle|b\rangle|z\rangle = \begin{cases} 
|\{u, v\}\rangle|b \oplus 1\rangle|z\rangle & \text{if } \{u, v\} \in E, \\
|\{u, v\}\rangle|b\rangle|z\rangle & \text{if } \{u, v\} \notin E,
\end{cases}
\]

where $\oplus$ denotes the bit parity. Consider a quantum algorithm that computes some property of $G$. We say that the algorithm uses $k$ queries if the operation $O_G$, which is given as an oracle, is called $k$ times by the algorithm.

We describe below two quantum query algorithms that we will use to construct our quantum protocol for $TF_{n,m}^3$ in the communication complexity setting.

**Quantum search with variable costs.** Let $X$ be a finite set of size $N$. Let $f_G: X \rightarrow \{0, 1\}$ be a Boolean function depending on the input graph $G$. The goal is to find an element $x \in X$ such that $f_G(x) = 1$ if such an element exists. Assume that, for each $x \in X$, there exists a checking procedure $P^x$ that computes $f_G(x)$ using $t_x$ queries to $O_G$ with high probability. When we use Grover search, this task can be completed with $O(\sqrt{N} \times t_{\text{max}})$ queries with high probability, where $t_{\text{max}} = \max_{x \in X} t_x$. Ambainis [3] proposed a more general quantum algorithm, which achieves this task using

\[
\tilde{O}\left(\sqrt{\sum_{x \in X} t_x^2}\right)
\]

queries with high probability. In this paper, we call this algorithm variable costs quantum search.

**Quantum walk over Johnson graphs.** Let $S$ be a finite set and $r$ be an integer such that $1 \leq r \leq |S|$. Let $f_G: X(S, r) \rightarrow \{0, 1\}$ be a Boolean function depending on a graph $G$. We say that a set $A \in X(S, r)$ is marked if $f_G(A) = 1$. Consider a task whose goal is to find a marked set, if such a set exists, or report that there is no marked set. Ambainis [2] developed the quantum walk search approach, which achieves this task using a quantum walk over a Johnson graph.

**Definition 2.1.** Let $X$ be a finite set and $k \in \{1, \ldots, |X|\}$. A Johnson graph $J(X, k)$ is an undirected graph with vertex set $X(X, k)$ where two vertices $R, R' \in X(X, k)$ are adjacent if and only if $|R \cap R'| = k - 1$.

The state of a quantum walk over a Johnson graph $J(S, r)$ corresponds to a vertex of the Johnson graph (i.e., to a set in $X(S, r)$). The key idea of the quantum walk search approach is that each state $A$ of the walk has a data structure $D(A)$, which in general depends on $G$. There are three costs of the walk to consider:

- **Set up cost $S$:** The worst case number of queries to $O_G$ needed to construct $D(A)$ for $A \in X(S, r)$.
- **Update cost $U$:** The worst case number of queries to $O_G$ needed to update $D(A)$ to $D(A')$ when one step of the quantum walk is performed (i.e., a state $A$ of the walk moves to $A'$ for some $A' \in X(S, r)$ such that $|A \cap A'| = r - 1$).
- **Checking cost $C$:** The worst case number of queries to $O_G$ needed to check if the current state $A$ is marked by using $D(A)$ (i.e., checking whether $f_G(A) = 1$).

Let $\varepsilon > 0$ be the fraction of marked states. The quantum walk search approach finds a marked state if such a state exists with quantum query complexity

\[
\tilde{O}\left(\frac{S + \frac{1}{\sqrt{\varepsilon}} (\sqrt{r} \times U + C)}{\sqrt{\varepsilon}}\right),
\]

with high probability (see [2, 15]).
2.3 Graph collision

Graph collision is a variant of collision problems such as element distinctness or two-to-one collision. In the quantum query complexity setting this problem is defined as follows. Given a known graph $G = (V, E)$ with $|V| = n$ and an oracle $f: V \rightarrow \{0, 1\}$, the graph collision problem asks whether there exists an edge $\{a, b\} \in E$ such that $f(a) = f(b) = 1$. The best known upper bound on the quantum query complexity of graph collision, obtained in [16] using quantum walks, is $\tilde{O}(n^{2/3})$. No lower bound better than the trivial $\Omega(\sqrt{n})$ is known.

In this paper, we consider the following distributed version of three-party graph collision, which is parametrized by two disjoint vertex sets $V_A, V_B$ such that $|V_A| = |V_B| = n$:

Three-Party Graph Collision, $GC_{V_A,V_B}^3$

- **Alice’s input:** Boolean function $f_A : V_A \rightarrow \{0, 1\}$
- **Bob’s input:** Boolean function $f_B : V_B \rightarrow \{0, 1\}$
- **Charlie’s input:** set of edges $E$ between $V_A$ and $V_B$
- **Output:** $GC_{V_A,V_B}^3(f_A, f_B, E) = \bigvee_{i,j} E(i)f_B(j)$

This problem can be solved using $\tilde{O}(n^{2/3})$ qubits of communication by implementing, using standard techniques (see, e.g., [5]) to convert a query algorithm into a quantum protocol, the quantum query algorithm mentioned above since Charlie knows completely the set of edges $E$ of the corresponding graph.

3 Upper Bound

In this section we show a quantum protocol for $TF_{n,m}^3$ that has $\tilde{O}(m^{7/12})$ communication complexity, which proves Theorem 1.

Let $G = (V, E)$, with $E$ distributed among Alice, Bob and Charlie, be the input of $TF_{n,m}^3$. Let $E_A$ be the edges owned by Alice, $E_B$ be the edges owned by Bob and $E_C$ be the edges owned by Charlie. We will write $V = \{v_1, \ldots, v_n\}$. Let $s$ be a parameter, to be chosen later, such that $0 \leq s \leq 1$.

3.1 Reduction to finding triangles in tripartite graphs

Consider the following tripartite graph $G'$. The set of vertices of $G'$ is the union of the three sets $I = \{v_1^1, \ldots, v_n^1\}$, $J = \{v_1^2, \ldots, v_n^2\}$, and $K = \{v_1^3, \ldots, v_n^3\}$. The set of edges of $G'$ is $E_A \cup E_B \cup E_C$, where $E_A$, $E_B$ and $E_C$ are constructed from $E$ as follows:

- Put edges $\{v_s^1, v_t^2\}$ and $\{v_t^1, v_s^2\}$ to $E_A$ if and only if $\{v_s, v_t\} \in E_A$.
- Put edges $\{v_s^1, v_t^2\}$ and $\{v_t^1, v_s^3\}$ to $E_B$ if and only if $\{v_s, v_t\} \in E_B$.
- Put edges $\{v_s^2, v_t^1\}$ and $\{v_t^2, v_s^3\}$ to $E_C$ if and only if $\{v_s, v_t\} \in E_C$.

Observe that, without communicating with each other, Alice, Bob and Charlie can construct the tripartite graph $G'$ in the following sense: Alice can create $E_A$, Bob can create $E_B$, and Charlie can create $E_C$.

Note that $G'$ contains a triangle if and only if $G$ contains a triangle. For instance, if the graph $G$ contains a triangle consisting of three vertices $v_a, v_b, v_c$ in $V$ such that Alice has the edge $\{v_a, v_b\} \in E_A$, Bob has the edge $\{v_a, v_c\} \in E_B$, and Charlie has the edge $\{v_b, v_c\} \in E_C$, then the tripartite graph $G'$ contains the triangle with three edges $\{v_a^1, v_b^2\} \in E_A$, $\{v_a^1, v_c^3\} \in E_B$ and $\{v_b^2, v_c^3\} \in E_C$. 

5
3.2 Protocol for dense graphs

The dense case is easy to deal with: we can simply combine Grover search (implemented in a distributed setting) with the protocol for graph collision mentioned in Section 2.3. This gives a quantum protocol with communication complexity $\tilde{O}(\sqrt{n} \times n^{2/3}) = O(n^{7/6})$. For later reference we state this upper bound as follows.

**Proposition 3.1.** The bounded-error quantum communication complexity of $TF_{n,n^2}$ is $\tilde{O}(n^{7/6})$.

3.3 Classifying the vertices of $G'$

For any vertex $v$ in $G'$, let us denote the degree of $v$ by $d_v$. For any $v \in I$, let us denote the set of neighbors in $J$ of $v$ by $N_J^I(v)$, and denote the set of neighbors in $K$ of $v$ by $N_K^I(v)$. For any $v \in J$, let us denote the set of neighbors in $I$ of $v$ by $N_I^J(v)$, and denote the set of neighbors in $K$ of $v$ by $N_K^J(v)$. For any $v \in K$, let us denote the set of neighbors in $I$ of $v$ by $N_I^K(v)$, and denote the set of neighbors in $J$ of $v$ by $N_J^K(v)$. Alice, Bob, and Charlie classify all vertices in $I$ into two sets:

$$I_h^s = \{ v \in I \mid |N_J^I(v)| \geq n^s \text{ or } |N_K^I(v)| \geq n^s \},$$

all vertices in $J$ into two sets:

$$J_h^s = \{ v \in J \mid |N_I^J(v)| \geq n^s \text{ or } |N_K^J(v)| \geq n^s \},$$

all vertices in $K$ into two sets:

$$K_h^s = \{ v \in K \mid |N_I^K(v)| \geq n^s \text{ or } |N_J^K(v)| \geq n^s \},$$

We will say that a vertex $v$ of $G'$ is $s$-high if $v \in I_h^s \cup J_h^s \cup K_h^s$, and say it is $s$-low if $v \in I_l^s \cup J_l^s \cup K_l^s$.

The classification of $I$ can be done with $O(\frac{n^s}{n^{7/6}})$ bits of communication as follows. Since Alice holds the set of edges $E_A$ between $I$ and $J$, Alice knows, with no communication, the set $\{ v \in I \mid |N_J^I(v)| \geq n^s \}$. Then Alice sends this set to both Bob and Charlie with $O(\frac{|E_A|}{n^{7/6}}) = O(\frac{n^s}{n^{7/6}})$ bits of communication. Since Bob holds the set of edges $E_B$ between $I$ and $K$, Bob knows, with no communication, the set $\{ v \in I \mid |N_K^I(v)| \geq n^s \}$, and then sends this set to both Alice and Charlie with $O(\frac{|E_B|}{n^{7/6}}) = O(\frac{n^s}{n^{7/6}})$ bits of communication. Thus they obtain the sets $I_h^s$ and $I_l^s$ with $O(\frac{n^s}{n^{7/6}})$-bit communication. Similarly, they can obtain the classifications of $J$ and $K$ using $O(\frac{n^s}{n^{7/6}})$ bits of communication.

3.4 Finding a graph with a low vertex

The following proposition is the main technical contribution of this paper.

**Proposition 3.2.** The existence of a triangle of $G'$ containing at least one $s$-low vertex can be checked in $\tilde{O}(\sqrt{mn}n^{s/6})$ qubits of communication.

*Proof.* Let us consider the case where Alice, Bob, and Charlie check if $G'$ has a triangle with an $s$-low vertex in $I_l^s$. In this case, Alice simulates Ambainis’ variable costs search over $I_l^s$. The goal is to find one vertex (in $I_l^s$) of a triangle of $G'$. For each $i \in I_l^s$, given the set of edges $E_C$, the checking procedure $P^s$ of the search decides if there exists an edge $\{j, k\} \in E_C$ such that $\{i, j, k\}$ is a triangle of $G'$. The checking procedure $P^s$ can be simulated as follows.

Let us fix $i \in I_l^s$. Let $q$ be a parameter to be chosen later such that $0 \leq q \leq 1$. Alice and Bob define two bijective functions: $g^A_A : \{1, \ldots, |N_J^I(i)|\} \rightarrow N_J^I(i)$, and $g^A_B : \{|N_J^I(i)| + 1, \ldots, |N_J^I(i)| +$
$|N'_K(i)| \rightarrow N'_L(i)$, respectively. Then Alice and Bob send $|N'_J(i)|$ and $|N'_K(i)|$ to Charlie. After receiving the two values $|N'_J(i)|$ and $|N'_K(i)|$, Charlie simulates the following quantum walk search $A'_W$ in order to check if there exists an edge in $E_C$ that forms a triangle of $G'$ with $i$. The walk $A'_W$ searches for a set $R \subseteq \mathcal{X}(\{1, \ldots, |N'_J(i)| + |N'_K(i)|\}, [(|N_J(i)| + |N_K(i)|)^q]) = \mathcal{X}(\{1, \ldots, d_i\}, \{d_i^q\})$ which contains two indices $x \in \{1, \ldots, |N'_J(i)|\}$ and $y \in \{\{N'_J(i) + 1, \ldots, |N'_J(i)| + |N'_K(i)|\}$ such that $(i, g'_A(x), g'_B(y))$ is a triangle of $G'$. When the set of marked state is not empty, the fraction of marked states is

$$\varepsilon = \Omega\left((|N'_J(i)| + |N'_K(i)|)^{2(q-1)}\right) = \Omega\left(d_i^2(q-1)\right).$$

The data structure $D(R)$ stores \{(x, g'_A(x)) | x \in R \cap \{1, \ldots, |N'_J(i)|\}\} and \{(y, g'_B(y)) | y \in R \cap \{\{N'_J(i) + 1, \ldots, |N'_J(i)| + |N'_K(i)|\}\}$. In order to construct this data structure $D(R)$ of the initial state of the walk, Charlie asks Alice to send the vertex $g'_A(r)$ to him if $r \leq |N'_J(i)|$, and asks Bob to send the vertex $g'_B(r)$ to him if $r > |N'_J(i)|$ for each $r \in R$. More precisely, for any $r \in R$, Alice and Bob perform the following unitary operators $O_{g'_A}, O_{g'_B}$ to the basis state $|r\rangle|0\rangle$, respectively, where $|0\rangle$ consisting of $\lfloor \log n \rfloor$ qubits. For any $r \in R$, the unitary operator $O_{g'_A}$ maps the basis state $|r\rangle|0\rangle$ to the state

$$O_{g'_A}|r\rangle|0\rangle = \left\{ \begin{array}{ll} |r\rangle|g'_A(r)\rangle & \text{if } r \leq |N'_J(i)|, \\ |r\rangle|0\rangle & \text{if } r > |N'_J(i)|. \end{array} \right.$$ 

Thus the setup communication cost of this walk is $S_C = \tilde{O}(|R|) = \tilde{O}(d_i^q)$ qubits. The update communication cost is $U_C = \tilde{O}(1)$ qubits, and the checking communication cost is $C_C = 0$. Thus Charlie can simulate, with high probability, the quantum walk search $A'_W$ with

$$\tilde{O}\left(S_C + \sqrt{\frac{1}{\varepsilon}} \{\sqrt{|R|} \times U_C + C_C\}\right) = \tilde{O}(d_i^q + d_i^{-q/2}),$$

(1) qubits of communication. Setting $q = \frac{2}{3}$ gives the upper bound $\tilde{O}(d_i^{2/3})$.

For each $i \in I^*_i$, Alice, Bob and Charlie can thus implement $D^i$ with $\tilde{O}(d_i^{2/3})$ qubits of communication. Alice can therefore simulate Ambainis’ variable costs search with

$$\tilde{O}\left(\sqrt{\sum_{i \in I^*_i} (d_i^{2/3})^2}\right).$$

qubits of communication. To analyze this upper bound, we divide the set of $s$-low vertices $I^*_i$ into subsets $I^*_i,p = \{i \in I^*_i | 2^{p-1} \leq d_i \leq 2^p\}$, for $p = 1, \ldots, \lfloor \log n \rfloor$. Note that $|I^*_i,p| = O\left(\frac{m}{2^{p-1}}\right)$, for each
\( p = 1, \ldots, \lfloor \log n \rfloor \). The quantum communication complexity of the quantum protocol is thus

\[
\tilde{O} \left( \sqrt{\sum_{i \in I_i^s} d_i^{4/3}} \right) = \tilde{O} \left( \sqrt{s \log n} \right)
\]

\[
= \tilde{O} \left( \sum_{p=1}^{\lfloor \log n \rfloor} |I_{p,p}^s| (2p)^{4/3} \right)
\]

\[
= \tilde{O} \left( \sum_{p=1}^{\lfloor \log n \rfloor} \frac{m}{2p-1} (2p)^{4/3} \right)
\]

\[
= \tilde{O} \left( \sqrt{s \log n} \cdot m \left(2^s \log n\right)^{1/3} \right)
\]

\[
= \tilde{O} \left( m(n^s)^{1/3} \right)
\]

\[
= \tilde{O} \left( \sqrt{mn^{s/6}} \right),
\]

as claimed. \( \square \)

### 3.5 Putting everything together

Checking if \( G' \) contains a triangle can be divided into four problems:

1. Checking if \( G' \) contains a triangle with one vertex in \( I_i^s \), another vertex in \( J \), and the other vertex in \( K \).
2. Checking if \( G' \) contains a triangle with one vertex in \( I_i^s \), another vertex in \( J_s^h \), and the other vertex in \( K \).
3. Checking if \( G' \) contains a triangle with one vertex in \( I_i^s \), another vertex in \( J_s^h \), and the other vertex in \( K_s^h \).
4. Checking if \( G' \) contains a triangle with one vertex in \( I_i^s \), another vertex in \( J_s^h \), the other vertex in \( K_s^h \).

Cases 1, 2 and 3 can be solved with \( \tilde{O}(\sqrt{mn^{s/6}}) \) qubits of communication, from Proposition 3.2. For case 4 (checking if \( G' \) contains a triangle with three \( s \)-high vertices), Alice, Bob, and Charlie directly use Proposition 3.1. Since \( I_h^s = O\left(\frac{m}{n^{3/2}}\right) \), \( J_h^s = O\left(\frac{m}{n^{s/2}}\right) \), and \( K_h^s = O\left(\frac{m}{n^{s/2}}\right) \), Case 4 can be solved with \( \tilde{O}\left(\left(\frac{m}{n^{s/2}}\right)^{7/6}\right) \) qubits of communication.

Thus the total communication cost of the quantum protocol for \( TF_{n,m}^3 \) is

\[
\tilde{O}\left(\frac{m}{n^{s/2}} + m^{1/2}n^{s/6} + \frac{m^{7/6}}{n^{7/6}}\right),
\]

which is optimized by taking \( s \) such that \( n^s = m^{1/2} \), giving the final quantum communication complexity of \( \tilde{O}(m^{7/12}) \).

### 4 Lower Bounds

In this section we give the proofs of Propositions 1.1 and 1.2. Let us denote by \( Q_{GC}(n) \) the quantum query complexity of graph collision, when parametrized by graphs with \( n \) vertices.
Proof of Proposition 1.1. From the construction of the protocol giving the bound of Proposition 3.1, it follows that there exists a quantum protocol which computes, with high probability, $\text{TF}^3_{n,n^2}$ with $\tilde{O}(\sqrt{n} \times Q_{\text{GC}}(n))$ qubits of communication. Thus, an $\Omega(n^{1+\epsilon})$ lower bound on the bounded quantum communication complexity of $\text{TF}^3_{n,n^2}$ for some $\epsilon > 0$ implies an $\Omega(n^{1/2+\epsilon})$ lower bound on the quantum query complexity of graph collision.

Proof of Proposition 1.2. Let $s$ be a parameter such that $0 \leq s \leq 1$. From the construction of the protocol giving the bound of Proposition 3.2, it follows that there exists a quantum communication protocol which computes $\text{TF}^3_{n,m}$ with the bounded-error quantum communication complexity

$$\tilde{O}\left(m^{1/2}n^{s/6} + \sqrt{\frac{m}{n^s}} \times Q_{\text{GC}}(m/n^s)\right).$$

Suppose an $\Omega(m^{4/7+\epsilon})$ lower bound on the bounded-error quantum communication complexity of $\text{TF}^3_{n,m}$ for some $\epsilon > 0$. Setting $n^s = m^{3/7+6\epsilon}$ gives the upper bound $\tilde{O}\left(m^{4/7+\epsilon} + m^{2/7-3\epsilon} \times Q_{\text{GC}}(m^{4/7-6\epsilon})\right)$.

This implies the lower bound $\Omega(n^{4/7+\epsilon})$ on the quantum query complexity of graph collision.
